# Methods to estimate the length effect on tensile strength parallel to the grain in Japanese larch 

Received: April 7, 2000 / Accepted: August 21, 2000

#### Abstract

To find a desirable method for estimating the length effect on tensile strength $\left(\sigma_{\mathrm{t}}\right)$, we used three methods to analyze the $\sigma_{\mathrm{t}}$ data from a Japanese larch (Larix kaempferi) small, clear specimen. These methods included a nonparametric method, the projection method of Hayashi, and a proposed method. The estimated length effect parameters $(g)$ by the nonparametric method were 0.0237 and 0.0626 for 50 th and 5 th percentile $\sigma_{\mathrm{t}}$ distributions, respectively. The projection method requires a standard $E_{\mathrm{f}}$ level ( $E^{*}$ : dynamic Young's modulus), arbitrarily chosen for calculating the $g$ value. The $g$ values from the projection method were 0.1122 for low $E^{*}, 0.0898$ for average $E^{*}$, and 0.0759 for high $E^{*}$. The estimated $g$ values by the proposed method using selected $\sigma_{\mathrm{t}}$ data were 0.1020 and 0.1838 for the 50th and 5th percentiles, respectively. Among the three methods, the nonparametric method did not consider the different distribution of Young's modulus among specimens, and the estimated length effect parameters $(g)$ by this method were small. The projection method reduced the influence of Young's modulus, but the length effect parameters varied with the $E^{*}$ level. The proposed method minimized the dependence on $E_{\mathrm{f}}$ distributions among specimens. We believe the latter method is desirable for estimating the length effect on tensile strength.

## Introduction

When evaluating strength properties of structural lumber used as engineered wood, ${ }^{1}$ tensile strength is usually an important factor. To estimate the tensile strength of structural lumber, the size effect in the length direction must be

[^0]considered, as there is a decreasing trend of tensile strength with increasing length of the specimen. Up to now, many researchers have focused on length effects on tensile strength for structural lumber. For example, the American Society for Testing and Materials (ASTM) ${ }^{2}$ gives a characteristic value (0.14) equivalent to the length effect parameter for adjusting the ultimate tensile stress parallel to the grain in visually graded dimension lumber. There are few reports about length effects on tensile strength for small clear specimens. Here we attempted to investigate length effects on tensile strength for small clear specimens.

In Japan, testing methods for wood, including the method to test tension parallel to grain, are specified by Japanese industrial standards (JIS). ${ }^{3}$ Because the test methods have prescribed the particular dimensions and shapes of specimens, we can easily compare various test data obtained by the same method. This is why the size effect had not been encountered before, as the standard test methods called for constant configuration, as Madsen ${ }^{4}$ described. There are few reports concerning the size effect on strength in small clear specimens. Among them, Madsen ${ }^{5}$ reported the size effects on bending strength in defect-free Douglas fir; and Masuda and Okohira ${ }^{6}$ explored the size effect on bending strength in western hemlock. Okohira et al. ${ }^{7,8}$ investigated the size effect on compressive strength in hinoki (Japanese cypress) and hemlock, as well as the width effect on the tensile strength of western hemlock. In this research, we focused on the length effect, although there are some empirical studies relative to failure theories. ${ }^{9}$

It is known that there are at least three methods ${ }^{4}$ for obtaining the length effect parameter: slope method, shape parameters, and fracture position. The slope method is based on the relation between the logarithm of strength ( $x$ ) and the logarithm of length ( $L$ ) (or depth or volume); the length effect parameter $g$ is calculated by $g=-\left\{\ln \left[x\left(L_{2}\right)\right]-\right.$ $\left.\ln \left[x\left(L_{1}\right)\right]\right\}\left\{\left\{\ln \left(L_{2}\right)-\ln \left(L_{1}\right)\right\}\right.$. This equation can be rewritten as $x\left(L_{2}\right)=x\left(L_{1}\right) \times\left(L_{2} L_{1}\right)^{-g}$. With the shape parameter method the length effect parameter is given as an inverse of the shape parameter ( $k$ ) of the fitted two-parameter Weibull distribution (2P-Weibull). Size effects have commonly been expressed as a function of $k$. According to

Madsen, ${ }^{10}$ the important feature should be $1 / k(=g)$, not $k$, as one wants to use these size effects for design purposes. The last method is applied for a bending test with a concentrated load in the center of the span.

In this study, we used the slope method to calculate length effect parameters and then three other methods to analyze them: the nonparametric method, the projection method proposed by Hayashi et al., ${ }^{11}$ and a proposed method. The objective of this study was to find a desirable method for estimating the length effect.

## Experiment

## Materials

Materials for tests were cut from six 87-year-old Japanese larch (Larix kaempferi) trees harvested at Togakushi in Nagano, Japan. The range of diameters at breast height was $32-43 \mathrm{~cm}$. We cut 2 m long logs from the sampled trees and obtained 25 mm thick and 150 mm wide samples from the logs. Details of the materials can be found in the report by Zhu et al. ${ }^{12}$ Then 360 mm (A), 390 mm (B), or 460 mm (C) long sticks were randomly cut from the air-dried lumber. All obtained samples were planed to a size that was 25 mm wide (radial direction) and 15 mm thick (tangential direction). For each sample we determined the annual ring width (ARW), density, and dynamic Young's modulus ( $E_{f}$ ) by the longitudinal vibration method. ${ }^{13}$

## Tensile test

Tensile test specimens were prepared from the samples according to JIS. ${ }^{3}$ There were three types of specimen: short (a), normal (b), and long (c); "normal" means the same shape as that specified in JIS. ${ }^{3}$ The numbers of specimens for groups a, b, and c were 60,56 , and 63 , respectively; and all of them were processed with the $A, B$, and $C$ samples. Figure 1 shows the shapes and dimensions for each type. The cross section of the thinnest part for all specimens was 5 mm thick and 25 mm wide; and the lengths of this part for $a, b$, and c specimens were 30,60 , and 120 mm , respectively. There are called spans in the following discussion. Using these specimens, we conducted static tensile tests parallel to the grain and determined the tensile strength $\left(\sigma_{\mathrm{t}}\right)$ for each specimen. The test was conducted using the universal testing machine, and the loading speed was kept at less than $200 \mathrm{~kg} / \mathrm{min}$. All specimens failed within the span. Tensile strength was calculated from the maximum load attained and the actual cross-sectional dimensions of the specimens.

## Results and discussion

## Tensile strength test

The dimensions, test spans, and properties of specimens are shown in Table 1. These values were obtained by measuring

Fig. 1. Specimens. a Short type, 30 mm span. b Normal type according to JIS, 60 mm span. c Long type, 120 mm span; R $425,425 \mathrm{~mm}$ radius
the samples before processing the specimens into the shape needed for the tensile tests. There were small differences in annual ring width or density among the specimens. Based on the $t$-test, there was no significant difference between specimens $b$ and $c$ in terms of the dynamic Young's modulus $\left(E_{\mathrm{f}}\right)$ at the $5 \%$ significance level $(|t|=0.153<1.982)$; there were significant differences between specimens a and b $(|t|=3.041>1.981)$ and specimens a and c $(|t|=2.814>$ 1.980).

Table 2 shows the tensile strength tests for each specimen. The distributions of $\sigma_{\mathrm{t}}$ are shown in Fig. 2. There were few differences among the $\mathrm{A}, \mathrm{B}$, and C specimens. Table 2 also shows the correlation coefficients between $\sigma_{\mathrm{t}}$ and other wood properties. Among them, the coefficients between $\sigma_{t}$ and $E_{\mathrm{f}}$ are the highest.

Generally, there should be a decreasing trend of tensile strength with increasing length of the specimens, but there seems to be no significant length effect based on above results. Based on the weakest link theory, we thought that the different distribution of $E_{\mathrm{f}}$ among specimens might influence the results. Hence we tried to estimate the length effect with several methods.

## Nonparametric method

We attempted to estimate the length effect on $\sigma_{\mathrm{t}}$ by the slope method. First, the 50th and 5th percentiles of the tensile strength distributions for each specimen were obtained by the nonparametric method according to ASTM standard D2915-94. ${ }^{14}$ Next, the length effect parameters were obtained by fitting regression curves, as shown in

Table 1. Dimension, test span, and properties of specimens

Fig. 3. The obtained parameters were 0.0237 and 0.0626 for the 50th and 5th percentiles, respectively. From above results, it could be found that the length effect seemed minimal by this method.

## Projection method

It is difficult to estimate precisely the size effect by comparing the obtained $\sigma_{\mathrm{t}}$ distributions for some specimens of vari-

Fig. 3. Length effects by the nonparametric percentile point estimate, Squares, 50th percentiles; triangles, 5th percentiles
ous lengths when their distributions of Young's modulus do not coincide well with each other. To solve this problem, Hayashi et al. ${ }^{11}$ proposed a method in which the length effect parameter was estimated using adjusted $\sigma_{\mathrm{t}}$ data for Young's modulus. First, we calculated the regression line using Young's modulus (MOE) and tensile strength (TS): TS $=a \times \mathrm{MOE}+b$ (where $a$ and $b$ are constants). Then we selected one MOE value as standard (MOE*). We then calculated [TS $-a \times\left(\mathrm{MOE}-\mathrm{MOE}^{*}\right)$ ] and used this value as the adjusted TS. The length effect parameter can then be

Fig. 4. Adjustment of $\sigma_{\mathrm{t}}$ data for standard Young's modulus ( $E^{*}$ ) level. (Each adjustment $\sigma_{\mathrm{t}}$ was obtained by sliding the original $\sigma_{\mathrm{t}}$ onto the standard $E$ level parallel to the regression line.) | c | 126.7 | 11.8 | 9.23 | 133.2 |

$k$ and $m$, shape and scale parameters of 2 P -Weibull, respectively
obtained as the slope (with a negative sign) of the linear regression line of the logarithm of the adjusted TS on the logarithm of the length. The concept of this method is summarized in Fig. 4. We might call this the projection method by setting a standard $E$ level, as all $\sigma_{\mathrm{t}}$ data were projected on the standard $E_{\mathrm{f}}\left(E^{*}\right)$ level as a screen with lights parallel to the regression line.

Figure 5 shows the relation between $E_{\mathrm{f}}$ and $\sigma_{\mathrm{t}}$ and the regression lines. To examine the effect of the $E^{*}$ level on the length effect parameter, we established three $E^{*}$ levels: low (mean minus SD of $E_{\mathrm{f}}$ distribution of all specimens); average (mean value); and high (mean plus SD). The adjustment of $\sigma_{\mathrm{t}}$ data for each specimen was carried out with the above method; and distributions of the adjusted $\sigma_{\mathrm{t}}$ data are shown in Table 3. The parameters of 2PWeibull in Table 3 were determined by the maximum likelihood method. Using the adjusted $\sigma_{\mathrm{t}}$ data, we obtained

\end{equation*}
$$

where $\sigma_{\mathrm{t}}^{*}$ is adjusted $\sigma_{\mathrm{t}}$ data (MPa), $L$ is the span $(\mathrm{cm}), r^{2}$ is the determination coefficient, and $\ln$ means natural loga-

Fig. 6. Length effect parameter estimated using adjusted $\sigma_{\mathrm{t}}$ data for various standard Young's moduli ( $E^{*}$ )
rithm. It was found that the negative correlations were significant at the $5 \%$ level. The length effect parameters were obtained by multiplying by -1 and the coefficients of $\ln (L)$. The estimated length effect parameters by the projection method were 0.1122 for low $E^{*}, 0.0898$ for average $E^{*}$, and 0.0759 for high $E^{*}$. The relation between $E^{*}$ and the length effect parameters by this method are shown in Fig. 6. With increasing $E^{*}$ level, the length effect parameters showed a decreasing trend.

From the above discussion, it is clear that the estimated length effect parameters depend on the $E^{*}$ level. If the mean Young's modulus values were always selected as $E^{*}$, the variation in the length effect parameters might be small. All these values were larger than the value for the 50th percentile ( 0.0237 ) by the nonparametric method. The differences of length effect parameters might be caused by the differences in $E_{\mathrm{f}}$ distributions among specimens.

## Proposed method

We attempted another method for estimating length effect parameters to minimize the dependence of the differences in $E_{\mathrm{f}}$ distributions among specimens. Each $\sigma_{\mathrm{t}}$ is selected if the coupled $E_{\mathrm{f}}$ value is within a particular range, and the length effect parameter is estimated using the distribution of the selected $\sigma_{\mathrm{t}}$ data set. In this study, the range of $E_{\mathrm{f}}$ was set at $11.0-14.0 \mathrm{GPa}$ for each specimen to compare it to the length effect of structural lumber reported in the literature. ${ }^{15} 2 \mathrm{P}$-Weibull was fit to the selected $\sigma_{\mathrm{t}}$ data sets, and the 50 th and 5 th percentiles were obtained using the 2 P Weibull distribution function for each specimen. The obtained parameters of 2 P -Weibull are shown in Table 4. Means and standard deviations for each specimen are also in Table 4.

In Fig. 7 the 50th and 5th percentiles of $\sigma_{t}$, obtained from the parameters of 2 P -Weibull, were plotted versus span

with regression curves of selected $\sigma_{\mathrm{t}}$ data. Figure 7 also shows the tensile strength (TS) of structural lumber noted in the literature. ${ }^{15}$ The estimated $g$ values using selected $\sigma_{\mathrm{t}}$ data were 0.1020 and 0.1838 for the 50th and 5th percentiles, respectively. The decreasing tendency with span for 50th

Fig. 8. Ratio of TS to $\sigma_{\mathrm{t}}$. Thick curve, 50th percentile; thin curve, 5th percentile
percentiles was weaker than for the 5th percentiles in small clear specimens, in contrast to structural lumber. To clarify the relation between defect-free wood and structural lumber for practical use, the TS/ $\sigma_{\mathrm{t}}$ was obtained using regression curves for the 50 th and 5 th percentiles. Figure 8 shows that the ratio for the 50th percentile distinctly decreased as the span increased below 50 cm , whereas a slight increase was observed for the 5 th percentiles. Above a $50-\mathrm{cm}$ span, the variation was relatively small; and both were roughly 0.5. The strength ratio, defined as the ratio of strength in structural lumber to that in a small clear specimen, had been given 0.39 and 0.47 for tension ${ }^{16}$ in ordinary-grade and highgrade lumber, respectively. It may be necessary to take into account the length effect when calculating the strength ratio.

## Conclusions

An experimental study was done to estimate the length effect on tensile strength $\left(\sigma_{\mathrm{t}}\right)$ in a Japanese larch small clear specimen. The estimated length effect parameters $(g)$ by the nonparametric method were 0.0237 and 0.0626 for the 50 th and 5 th percentiles, respectively. The $g$ values from the projection method, based on establishing a standard $E_{\mathrm{f}}\left(E^{*}\right)$ level, were 0.1122 for low $E^{*}, 0.0898$ for average $E^{*}$, and
0.0759 for high $E^{*}$. The estimated $g$ values by the proposed method using selected $\sigma_{\mathrm{t}}$ data were 0.1020 and 0.1838 for the 50 th and 5 th percentiles, respectively. Among the three methods, the nonparametric technique did not consider the different distributions of Young's modulus among specimens, and the estimated length effect parameters $(g)$ by this method were small. The projection method reduced the influence of Young's modulus, but the length effect parameters varied with the $E^{*}$ level. The proposed method minimized the dependence on $E_{\mathrm{f}}$ distributions among specimens. We think the latter is a desirable method for estimating the length effect on tensile strength.
